ACKNOWLEDGMENT

The estimates of the future population of the United States were prepared for the Committee on Population Problems by Warren S. Thompson and P. K. Whelpton of the Scripps Foundation for Research in Population Problems.

EXECUTIVE OFFICE OF THE PRESIDENT,
NATIONAL RESOURCES PLANNING BOARD,
Washington, D. C., August 24, 1943.

The PRESIDENT,
The WHITE HOUSE.

MY DEAR MR. PRESIDENT:

We have the honor to transmit a report on "Estimates of the Future Population of the United States," prepared for our Committee on Population Problems by the Scripps Foundation for Research in Population Problems.

Forecasts of the growth and distribution of population are obviously basic to all plans for development of the resources of the nation. In its 1934 Report, the National Resources Board included some estimates of population trends prepared with the help of this same Foundation, and those estimates were further developed in a series of reports in 1936 and 1937, prepared in connection with our study of "The Problems of a Changing Population." These previous estimates were based on the 1930 Census.

When the materials for the 1940 Census became available, our Science Committee recommended that our prior estimates should be brought up to date in the light of this new evidence. We were fortunate to be able to arrange with the Scripps Foundation for the preparation of the new estimates contained in this report.

Sincerely yours,

FREDERIC A. DELANO,
Chairman.
CHARLES E. MERRIAM
GEORGE F. YANTIS

INTRODUCTION

Revision of earlier estimates

The present set of estimates of the future population of the United States is the third to be prepared for the National Resources Planning Board by Warren S. Thompson and P. K. Whelpton of the Scripps Foundation for Research in Population Problems. Earlier estimates were made in 1934 and 1937.¹ Although only a few years have elapsed since the publication of the more recent of these preceding estimates, it has become apparent that, quite apart from the war, certain changes have been taking place to alter the outlook for population in the United States. Among the new factors that are affecting the future size and composition of the population are the continuance through 1942 of the upward turn of the birth rate that began in the middle 1930's, the introduction of the new chemotherapy with its promise of further reduction in mortality, the relatively favorable course of Negro mortality in recent years, the progressively greater concentration of childbearing in the earlier years of marriage, and considerable advances in the science of nutrition. These developments alone, without the intervention of the war, would have necessitated a revision of earlier estimates of future population. The departure from the previously indicated trends will be further accentuated by wartime conditions. Although the precise nature and extent of the war's effect on population are not predictable at the present time, there will unquestionably be both temporary and lasting effects on vital trends in the United States.

Because of the very considerable changes that have occurred since the publication of the earlier data by the National Resources Committee, it has become desirable to prepare new estimates of future population. These new estimates, based on the 1940 census, are in effect a statement of the significance of the recent vital changes in terms of the probable future size and composition of the population of the United States.

Form of the estimates

Twelve series of estimates have been prepared, each based on a set of assumptions with respect to the course of fertility, mortality, and immigration. As in the

previously published estimates, three alternative assumptions are made with respect to fertility, these being designated as high, medium, and low. High, medium, and low assumptions are also made for the course of mortality. The effect of an average net immigration of 100,000 foreign-born whites per annum, beginning in 1945, is estimated under three combinations of fertility and mortality assumptions.

With regard to the detail in which the estimates are available, the figures are presented separately by sex for each of three color and nativity groups, these being native-born white, foreign-born white, and colored. This division differs in one respect from the preceding estimates, in which the colored were classified into Negroes and other colored people. In conformity with the census practice, Mexicans were included among "other colored" in the earlier estimates and among the whites in the present series. As before, the estimates are given by 5-year age groups and at 5-year intervals, but the projection of population trends is extended in the present estimates up to the year 2000. In accordance with the preceding estimates, two figures are given in each case for the 0-4 age group, one being the estimated total number under 5 years of age, the other being a smaller number which reflects the underenumeration of young children by the census. There are therefore two estimates of total population at each quinquennial interval, one a higher or "true" figure and the other corresponding to the expected census count.

Interpretation of the estimates

Some care must be exercised in the use and interpretation of these estimates. It is to be emphasized that they are not predictions of future population size, nor are they to be assumed to indicate the probable sex and age structure. They are, strictly speaking, merely statements of what the size and the sex, age, color, and nativity composition of the population would be at specified future times if birth rates, death rates, and immigration were to follow certain specified trends. While it is true that the fertility and mortality assumptions have been chosen with regard to the indicated trends of vital rates, the purpose of the estimates is to show the approximate range within which future popu-

¹ See National Resources Committee, *Population Statistics, 1. National Data, 1937*; also *The Problems of a Changing Population, 1938*, pp. 22-27, and *Estimates of Future Population by States, 1934*.

lation would fall under the influence of current trends, rather than to arrive at a single most probable figure.

In the second place, the revised estimates when compared with the previously published material give evidence of the predictable net effect, in terms of future numbers and composition, of the recent vital changes.

Thirdly, the estimates in their unadjusted form, without modification for war losses, will serve as a bench mark against which the demographic effects of the war and of subsequent changes in fertility and mortality can be judged in later years.

In the fourth place, such estimates, by demonstrating the numerical effect of different birth rates, death rates, and amounts of immigration, provide a basis for judging how great a departure from the assumed trends would be required to give a different population total or a different composition at some future time. While there is no immediate prospect of such an application in the United States, there are several European countries in which it has come to be considered a matter of national interest to maintain a certain population size or rate of natural increase.

Finally, these national estimates provide a frame of reference within which corresponding data may be prepared for smaller units such as regions, States, or cities. Although population changes in these smaller areas will depend primarily on migration within the United States, the opportunity of any area to draw on or to contribute

to this migration will be affected by national population trends.

The usefulness of the estimates of future population for any of the above purposes depends in large measure on the reasonableness of the underlying assumptions on which the new tables are constructed. In order to facilitate the use of the estimates, a detailed statement of these assumptions is given below. Mortality trends are discussed in section A. A similar account of the background of the fertility assumptions is given in section B. In section C, the underenumeration of children is discussed. The method used to show the effect of immigration on the growth and composition of the population is explained in section D. Since there is little basis for estimating the course of immigration, the procedure that has been followed is to assume a fixed amount for each 5-year period and to compute the resultant population. From this material the effect of any multiple or fraction of this amount of immigration can be ascertained. In section E is a discussion of the problem of making allowance for the effects of the war. In further commentary on the estimates of future population, a summarization of some of the prospective changes is given in the later sections of the text. Both the explanation of the underlying assumptions and the discussion of the prospective changes are based directly on statements of method and analyses that have been prepared by Thompson and Whelpton.

STATEMENT OF ASSUMPTIONS

A. MORTALITY TRENDS, 1940-2000

Mortality trends in the United States

Although the future course of mortality rates in the United States will be in large measure dependent on changes in the general standard of living, on the level at which public health services are maintained, and on advances in medical science and nutrition, the prospects for further reduction of death rates can best be judged from a consideration of the past trends of mortality. Unfortunately for this purpose, the record of mortality within the United States has been far from complete. Although an official record of deaths has been kept in a few States for over a hundred years, it is only within comparatively recent years that the reporting of deaths can be assumed to have attained 90 percent or more of completeness for the country as a whole. It was in fact not until 1933 that the death registration area, for which the standard is a reporting of at least 90 percent of all deaths, came to cover the entire United States. The completeness with which deaths are registered is known to vary widely between different sections of the population and between different parts of the country. For these reasons, trends of mortality cannot be followed over any considerable period for the country as a whole, but only for those States which were admitted earliest to the death registration area.

During the last 40 years and more there has been a striking decline in the death rates of children and young adults within the death registration area (see table A 1). For white males in the original registration States, the 1929-31 death rates are seen to be less than half those of 1900-02 at nearly every age up to 40 and less than one-third as large at ages 1 to 4. Further substantial declines occurred among native white males in the entire United States during the 1930's, the 1939-40 death rates being from 20 to 45 percent below those for 1929-31 at nearly every age under 40. Improvement in the middle years of life was much less marked. At ages 50-54 for example the decline from 1900-02 to 1929-31 was less than 7 percent, and from 1929-30 to 1939-41 was barely 5 percent. Among those 60 and over, death rates remained relatively unchanged, being somewhat higher in 1929-31 than in 1900-02 but re-

duced slightly during the 1930's. At each age the death rates for females followed a similar trend, though in the majority of cases the declines slightly exceeded those of males.

TABLE A 1.—*Death Rates and Average Future Lifetime of White Males at Selected Ages in the Death Registration States, 1900-1902 to 1929-31, and of Native White Males in the United States, 1929-30 and 1939-40*

¹ Maine, New Hampshire, Vermont, Massachusetts, Rhode Island, Connecticut, New York, New Jersey, Indiana, Michigan, and District of Columbia. No adjustment has been made for incomplete registration of deaths.

² Values for average future lifetime for these years are taken from "United States Life Tables," Department of Commerce, Bureau of the Census, Washington, G. P. O., 1936.

³ Values for average future lifetime for this year are computed from "United States Abridged Life Tables, 1919-20," Department of Commerce, Bureau of the Census, Washington, G. P. O., 1923.

⁴ Computed by the Scripps Foundation for Research in Population Problems. Registered deaths have been increased by 3.6 percent in 1929-30 and 3.1 percent in 1939-40 to allow for incomplete registration, and the number of children under 5 increased by 7 percent to allow for underenumeration in the census. South Dakota and Texas are not included in 1929-30.

⁵ Deaths per year during age period per 1,000 persons alive at midpoint of age period.

A summary of the influence of these death rate changes on the length of life of an average individual is given in the lower section of table A 1. With the mortality rates of 1939-40 the average native white male would live 62.5 years, approximately 14 years longer than with the 1900-02 rates. Those reaching age 20 had 47.6 years of life remaining according to the 1939-40 figure, a gain of about 5 years. Future longevity at age 40 increased by nearly 2 years to 29.9. At

¹ Deaths in 1940 during age period per 1,000 persons alive at midpoint of age period. Deaths registered in the United States have been increased by 3.1 percent to allow for incomplete registration. In the States included in the table the completeness of the registration of deaths is well above that for the Nation, hence State deaths have not been adjusted.

ages above 50 the average future lifetime lengthened little, if any, as would be expected from the slight change in the corresponding death rates.

Significantly greater progress in reducing mortality and in lengthening life has been made in some States than in others. For white males under 1 the 1940 death rate was lowest in Oregon, more than 25 percent below the average for the United States (42.8 per thousand, compared to 58.6). At ages 1 to 4 Connecticut was the low State, its rate of 1.7 being only a little more than half that of 2.9 for the Nation. A similar situation was found at each age from 5 to 70, the State with lowest rate (Connecticut, Rhode Island, North Dakota, or South Dakota) being 30 to 55 percent below the United States average (see table A 2). At ages above 70 the differential narrowed, the lowest rate at 70 to 74 (57.0 in South Dakota) being less than 20 percent below the United States rate of 70.1. For white females the general pattern was much the same, but the differences were slightly smaller at most ages.

TABLE A 3.—*Average Years of Life Remaining at Death Rates of United States, 1939-40 and of Lowest States, 1940*¹

Exact age	White males			White females		
	Average years of life remaining at death rates of—		Difference	Average years of life remaining at death rates of—		Difference
	United States	Lowest State		United States	Lowest State	
0	62.0	68.0	6.0	66.5	71.5	5.0
20	47.3	51.9	4.6	50.8	54.5	3.7
40	29.6	33.3	3.7	32.8	35.7	2.9
60	14.7	16.8	2.1	16.6	18.5	1.9

¹ Based on death rates in table A 2.

If the death rates at each age in the entire Nation could be reduced to the lowest figure reached by any State in 1940 the average length of life would be increased significantly. For white males it would be 68 years, an increase of 6 years over the actual national figure (see table A 3), and for white females it would be 71.5 years, an increase of 5 years. Gains at older ages

would be smaller in numbers of years, though relatively larger. White males aged 20 would have 4.6 years added to their lives, those aged 40 would gain 3.7 years, and even the 60-year-olds would live 2.1 years longer. For white females the corresponding figures are 3.7, 2.9, and 1.9 years.

During recent decades the States with low death rates at any given time have shown fairly well what the death rates of other States and the Nation would be a few years later. In general, national rates have followed those of the leading States most closely at the younger ages, and lagged the most at the older ages. For native white males at ages under 15 the lag has been less than 10 years, the low death rates for Minnesota and Kansas during 1920-21 being surpassed by the Nation before the end of the 1920 decade, and the low rates for these States during 1928-29 being surpassed by the Nation during the middle of the 1930's (see table A 4). At ages 40-44 the leading States have been about 20 years ahead. The rate for the United States during 1928-29 was not quite as low as the Minnesota rate during 1910-11, neither was the national rate during 1938-39 quite as low as the 1920-21 rate in that State or in Kansas. At older ages the lag exceeds 40 years. Even now the death rates for the United States at most ages above 50 are not as low as those of Indiana during 1900-02.

If the future course of mortality for the individual States and the Nation as a whole resembles that just described, the national death rate for ages under 15 will be reduced to the 1940 level of the lowest States before 1950, and before 1960 for ages 15 to 44, but for the older ages the record of the best States in 1940 will not be equalled before the end of the century. To the extent that the lowest rates are affected by some under-reporting of deaths and that the completeness of reporting increases in the course of time, this schedule of reduction of mortality will be more difficult to achieve. It is also recognized that some sections of the United States enjoy special advantages which are reflected in lower mortality and which may be beyond the reach of the country as a whole. This does not mean, however,

that the increase in average duration of life shown in table A 3 is unobtainable. On the contrary, it is to be expected that death rates at the younger ages will continue to decline after 1950 and 1960, and that these reductions of mortality will offset or more than offset any failure to attain the record of the most favored States in the upper age groups. In short, to judge from the experience of the States with the lowest mortality it should be possible to lower the death rates of the white population of the United States so that by the year 2000 the average male will live more than 68 years, and the average female more than 71.5 years.

Mortality trends in other countries

Several countries have surpassed the United States in the average length of life of their citizens. In four countries the average white male at birth can look forward to a lifetime in excess of the 62-year average for the United States, the highest figure being 65.5 years for New Zealand (see table A 5). At age 20 the United States ranks no better than ninth, and is in a progressively less favorable position with respect to the higher age groups. Comparisons of the average length of life of white females are somewhat more favorable to the United States, although this country is by no means in the leading position.

Although New Zealand leads in average length of life, its specific death rates are by no means lowest at all age levels. It exceeds all other countries for children under 5, but at ages over 15 has the lowest death rates only for females aged 15 to 19 and 50 to 54 (see table A 6). At other ages the first position is held by Norway, the Netherlands, or Denmark, with Australia and Sweden occasionally in the second place. At no age level does the United States rank first or second. Certain States, however, compare more favorably with the leading foreign countries. For the first year of life New Zealand far surpasses Oregon, but at most ages between 1 and 60 the best State has attained a death rate as low or lower than the best foreign country (compare tables A 2 and A 6). At the upper

age levels the best States again fall behind the foreign record.

In the past the course of mortality in the younger age groups in the leading foreign countries has to some ex-

¹ Average annual deaths during age period per 1,000 persons alive at midpoint of age period. Death rates for United States adjusted for incomplete registration (see footnote to Table A 1), but no allowance made for underenumeration of children in the census. 1940 death rates by States available for white males, but not for native white males, at time of writing (February 1943).

² Indiana and Massachusetts were in the death registration area when it was organized in 1903.

³ These rates are for all males, of whom about 91 percent were native born in Indiana and about 68 percent were native born in Massachusetts.

⁴ Kansas was admitted to the death registration area in 1914, Minnesota in 1910, and Oregon in 1918.

tent foreshadowed the trend of mortality in the United States. During the 1930's our infant mortality rates were similar to those of New Zealand 20 years earlier (compare tables A 1 and A 8). At ages 1 to 24 we followed the leading countries more closely, our rates during the 1930's resembling those of New Zealand and Denmark some 5 to 15 years before. Above age 25 the lag increases, until in the age range of 60 and 70 it is necessary to go back to 1880 or earlier to find death rates in Norway as high as those of the United States at the present time.

TABLE A 7.—*Average Years of Life Remaining at Death Rates of United States, 1939-40, and of Lowest Country Between 1930 and 1940*¹

60.....	14.7	17.3	2.6	16.6	18.6	2.0

¹ Based on death rates in table A 6.

There can be no assurance that the trend of mortality in the United States will continue to resemble that of foreign countries as it has in the past. The lowest foreign rates, however, like the lowest State rates, do in any event represent attainable levels. As such they provide a basis for estimating the possible lowering of the general level of mortality. If the death rate at each age were to be reduced to the lowest level reached by any foreign country, the average white male in the United States would live 68.6 years, and the average white female 70.9 years, these being increases of 6.6 and 4.4 years over the present level (see table A 7). These figures differ only fractionally from those obtained above, using the mortality of the leading States.

To summarize, it may be difficult if not actually impossible for the United States to reduce the death rate

in the upper-age groups down to the lowest points currently maintained in the leading States and foreign countries. In contrast, however, it should be quite feasible during the next 60 years to reduce the mortality among children and young adults down to or below the present State and national minimum levels. Since improvement of mortality at the younger ages has much

¹ Deaths during age period per 1,000 persons alive at midpoint of age period.² From "Statistical Year-Book of the League of Nations, 1940-41," Geneva, 1941.³ From "Annuaire Statistique de la Norvege, 1931," Oslo, 1931; and "Statistical Year-Book of the League of Nations."

more effect on the average length of life than improvement at the upper ages, the better outlook for attaining or surpassing the present record low points of mortality among young people should more than compensate for the poorer prospect for comparable improvement of mortality at the higher ages. It is therefore entirely conceivable that by the year 2000 the national averages for the length of life will have exceeded 68 and 71 years, a greater average longevity than now prevails in any considerable body of people.

Mortality trends by cause of death

An examination of trends in mortality by specific causes gives further evidence on the opportunity for extension of the average length of life. Through a combination of scientific progress, public health practice, and general economic betterment, certain diseases which were important causes of death 40 years ago have been almost eliminated, while the mortality from others has been greatly reduced. Typhoid fever, meningitis, and diphtheria each killed more than 30 persons out of every 100,000 of population in 1900, but now take a toll of only 1 or 2 (see table A 9). The bronchitis and broncho pneumonia death rate has been reduced by a similar absolute amount in the same period, from almost 70 to less than 35, and the pneumonia and influenza rate still more, from 155 down to 60. The largest reduction of all is in tuberculosis mortality, the rate for which has been cut from over 170 to less than 50. A numerically smaller but proportionately larger reduction has been achieved in diarrhea and enteritis, from 112 to only 13 deaths per 100,000 persons per annum. The effect on average longevity of this latter saving of life is particularly marked since the greater part of the mortality from the intestinal diseases occurred among young children.

In contrast to the large measure of success achieved in the control of mortality due to epidemic and infectious diseases, there has been relatively little reduction in the rate of deaths from certain other causes. Accidents, cerebral hemorrhage, and softening of the brain

are each at about the same level as around the beginning of the century, while cancer and the diseases of the circulatory system kill at about twice the former rate. In part the greater incidence of cancer and of certain of the so-called degenerative diseases is apparent rather than real, because of the more complete diagnosis of these causes of death and because of the increasing proportion of the population in the older age groups where they are most prevalent. Quite apart from these influences, however, some real increase in certain causes of death has occurred.

Whether or not death rates will decline substantially during the next 50 years will depend in part on the continuation of the progress made in controlling diseases such as tuberculosis, influenza, and pneumonia. Here the outlook is favorable, for the more widespread utilization of present knowledge of the causes and control of these diseases would permit a substantial reduction below present levels. There is also a reasonable expectation that more effective measures for the control of these diseases will be developed, and that public health programs will be intensified and will be extended to cover larger sections of the population. Furthermore, it is not unlikely that a more effective control of diseases of infectious origin will have not only a direct effect on the level of mortality but will also have an important secondary effect in reducing the amount of impairment produced by nonfatal but nevertheless serious disease.

Although the degenerative diseases have not as yet been brought under control, there is nevertheless con-

tinued hope for the future. As mentioned above, the control of damaging infectious diseases such as scarlet fever, diphtheria, typhoid fever, gonorrhea, and syphilis should result eventually in a substantial reduction of the organic impairments and after-effects so common with such diseases. As these sequelae are reduced in frequency there should be a reduction in the number of organic break-downs or a postponement of these break-downs until later in life. In combination with improved techniques for early diagnosis and for treatment, there may therefore be some reduction in the mortality from the degenerative diseases even without the discovery of improved methods for their prevention or treatment.

Hypothetical mortality trends, 1940 to 2000

The material presented above leads to the conclusion that in the United States the death rates at the younger ages will be much lower by the year 2000 than in 1940, somewhat lower at the middle age groups, and only slightly if at all lower at the higher ages. The material cannot indicate, however, exactly how large the reductions will be nor how rapidly they will occur. It has therefore seemed desirable in the preparation of the estimates of future population to make three alterna-

tive sets of mortality assumptions, designated as "high mortality," "low mortality," and "medium mortality," the first representing the least decline in the age-specific death rates that seems probable, the second the largest decline that is considered reasonable, and the third a position approximately midway between the extremes.

With each of these assumptions it is possible to extrapolate past trends by 5- or 10-year intervals according to some formula and to arrive at hypothetical death rates for the year 2000. An alternative procedure is to study past trends and the likelihood of future changes, form an opinion as to the death rates to be expected in 2000, and obtain rates for intervening years by interpolation. The former method may seem to have the advantage of being less influenced by personal bias, but the personal element would nevertheless remain in the choice between two or more formulas fitting the past trends equally well by giving different results for the future. More important, the extrapolation of past trends according to such formulas might show future trends which seemed incompatible with present knowledge regarding causes of death and means of controlling them. After some experimentation with both methods, the second alternative was chosen as the more desirable

¹ For basis of computing rates see table A 1, note 4.

² Deaths per year during age period per 1,000 persons alive at midpoint of age period.

for the purpose at hand. High, medium, and low death rates of native white males were selected for the year 2000, rates for preceding years obtained by interpolation, and the corresponding rates for native white females, and foreign-born and colored males and females obtained by narrowing the differential between each of these groups and the native white males.¹ The resulting rates are given in table A 10.

After the hypothetical death rates were set for the year 2000, trend lines were chosen for interpolation over the period from 1940 up to the end of the century. It was assumed that the greater part of the decline of mortality would occur by 1990, and that the trend lines would therefore be nearly horizontal by 2000, the minimum rates being only slightly under the rate for that year. Experimentation with several conventional types of curves indicated that for most ages a simple logistic curve would best meet this requirement, pass through the observed rates for 1929-30 and 1939-40 and the assumed rates for 2000, and give reasonable values for years prior to 1929. This type of curve was accordingly used in interpolation for the high mortality assumption, at all ages, and for the low assumptions at ages under 40. At higher age levels for the low mortality assumption simple logistic curves gave values that were much too high when projected back to years before 1929, so that it was necessary to modify them empirically to decrease the rate of decline during the decades immediately preceding 1930 and following 1940. The medium trend values were set approximately midway between the high and the low series.

The hypothetical mortality trends given by this procedure are characterized by a rapid decrease at the lower ages and a leveling off in the upper age groups (see fig. 1). This pattern was followed exactly by the high mortality assumptions, which provided for a 45-percent reduction in infant mortality rates between 1940 and 2000 and a gradually diminishing reduction until age 60, above which point a continuation of the 1939-40 death rates was assumed. The high mortality assumptions for the year 2000 were somewhat below the rates attained by any foreign country at ages under 30, but the differences were not large numerically (see tables A 6 and A 10). Only for the first year of life and between age 10 and 15 were the high mortality assumptions for 2000 less than the lowest state rates in 1940. With this mortality the average future lifetime would be increased to 66.2 years at birth, 49.1 at age 20, 30.6 at age 40, and 14.9 at age 60. This is considered the least improvement that is to be expected.

¹ While accepting full responsibility for the mortality rate assumptions that were adopted, Thompson and Whelpton express their appreciation for suggestions received from W. R. Williamson of the Social Security Board, Leon E. Truesdell and Halbert L. Dunn of the Bureau of the Census, and Harold F. Dorn of the United States Public Health Service.

A different age pattern of mortality reduction was followed in the low mortality assumptions. Here the hypothetical reduction of the death rates between 1939-40 and 2000 was 60 percent for infants, rising to 75 percent in the teen ages and early adult life, then falling to 10 percent improvement between age 75 and 80. The most considerable departure from the present record low point of mortality occurs under 1 year of age, the rate assumed for 2000 (19.7 per 1,000) being nearly 15 points below the recent New Zealand rate (34.5 per 1,000). Between ages 1 and 70 the differences could not be large in absolute numbers for the rates are small, but they exceeded 60 percent at ages 10 to 15, and 30 percent at other ages under 60. If these low rates were to prevail, the average future lifetime in 2000 would be 72.1 years at birth, 54.1 years at age 20, 34.9 years at age 40, and 17.3 years at age 60. To achieve such longevity seems within the range of possibility, but it will require outstanding progress in medicine and public health.

The smaller percentage decrease of the infant death rate than of mortality at the immediately succeeding ages in the low mortality assumptions needs explanation. In recent years more than 30 percent of the infant deaths have been due to premature birth and nearly 10 percent to congenital malformations. While infant death rates for almost all other causes have been reduced sharply since 1900, these two causes have remained almost unaffected. Unless knowledge of nutrition and of other factors affecting prenatal growth is very greatly increased, there will be little decrease in the incidence of premature births and congenital malformations. Between the ages of 1 and 45, however, the irreducible minimum in the light of present and anticipated future knowledge is lower relative to the current level of mortality, and hence large percentage decreases still appear possible.

In the medium assumptions the percentage declines of death rates from 1939-40 to 2000 are approximately midway between those of the high and low assumptions. They result in an average future lifetime for native white males of 68.5 years at birth, 50.8 years at age 20, 32.0 years at age 40, and 15.3 years at age 60. The figure for infants is approximately the same as that based on the lowest death rates already achieved by a State or foreign nation (68.0 and 68.6 years respectively (tables A 3 and A 7). At adult ages, however, the medium values for future lifetime are less than those of the leading States or nations. This difference increases with age, the medium expectancy of 15.3 years at age 60 comparing with 16.8 years for the low State combination, and with 17.3 years for the low nations.

As mentioned earlier, the death rates for native white males were used as the basis for obtaining the rates for other groups. Three principles were followed in this

FIGURE 1.—Trend of the death rates of white males in the United States, in selected States, and in foreign countries, 1900 to 1940; estimated high, medium, and low mortality trends in the United States, 1940 to 2000.

connection. The first is that past differences between the death rates of native white, foreign white, and colored persons of the same sex are due chiefly to differences in socio-economic status rather than to inherent biological differences, and hence are subject in large measure to human control. The second is that an important part of the difference between the death rates of males and females of the same race and nativity groups is due to biological differences which are not subject to this measure of control. Although these two principles cannot be proved conclusively, they are supported by the available information. The third principle is that the larger the decline in the native white death rate, the smaller the differentials will become. This is derived from the first two, for a larger decline implies a greater control, and hence an approach toward the biological minimum of mortality.

In accordance with these principles the foreign-born white males and the colored males were assigned death rates for the year 2000 which exceeded those of the native white males at each age level by a specified fraction of the corresponding percentage difference in 1939-40. In the high assumptions the fraction used was three-fourths, in the medium assumptions it was one-half, and in the low assumptions it was one-fourth. The corresponding fractions for years intervening between 1940 and 2000 were obtained by straight line interpolation. Since the mortality of foreign-born males is lower than that of colored males at the present time, this procedure gave death rates for colored males which decreased more rapidly than those for the foreign-

born males, which in turn decreased more rapidly than did those of the native white males.

Death rates for native white, foreign-born white, and colored females were obtained from the corresponding rates for males. In the high mortality assumptions the percentage by which the male death rate exceeded the female death rate at each age was left unchanged. In the medium assumptions it was reduced by one-sixth between 1940 and 2000, and in the low assumptions it was reduced by one-third.

An abridged statement of the mortality assumptions, in the form of life table functions, is given in table 1. The net effect of these assumptions is to be seen in the tabulated estimates of future population. For example, the population given by the medium trend of fertility would range from 153,672,000 to 166,164,000 in the year 2000, depending on whether the high mortality or the low mortality trend was followed. The extreme range of mortality assumptions thus gives a difference of some twelve and a half million inhabitants at the end of the century.

The effect of other mortality trends on the size and composition of the future population can be calculated roughly by interpolating or extrapolating the differences between the results obtained under the three sets of mortality assumptions. While it is not expected that the actual course of mortality in the future will follow the assumed trends, it is believed that it will fall between the high and the low, being nearest to the medium series.

B. FERTILITY TRENDS, 1940-2000

Fertility trends in the United States

It is more difficult to judge the probable future course of fertility than it is that of mortality. While it is true that considerable fluctuation may still occur in the death rate under the conditions of modern civilization, notably with the occurrence of epidemics or with the outbreak of wars, most changes have occurred gradually with the development of medical and sanitary sciences. The birth rate in contrast is capable of considerable variation, being more directly dependent on individual behavior. Changing economic and social conditions not only determine the opportunity that people have for marrying and for raising families, but also influence their attitudes toward assuming these responsibilities. For this reason an analysis of past trends of fertility, while aiding in the formation of opinion concerning future developments, is not in itself sufficient but must be supplemented with more information on underlying causes and attitudes than in the case of mortality assumptions.

The recording of births in the United States has been

and probably still is less complete than the recording of deaths. The birth registration area was not formed until 1915, at which time it included only 10 States and the District of Columbia, growing to 23 States in 1920, to 46 in 1930, and becoming Nation-wide in 1933. It is only during the last decade, then, that birth data have been available for the entire United States. It is fortunate, therefore, that another measure of fertility, the ratio of children to women as given in the decennial census, is available as far back as 1800. In its customary form this is expressed as the ratio of the number of children under five to women within the childbearing period. As such this ratio is based on the births in the 5-year period preceding the census date, and is affected by child mortality as well as by fertility.

Caution must be exercised in the use and interpretation of both birth rates and the ratio of children to women, in particular because of some under-registration of births and some under-enumeration of young children. According to a comparison between 1940 census schedules and birth certificates, approximately 6.2

percent of the white births and 18.1 percent of the colored births occurring between December 1, 1939 and March 31, 1940 had not been registered.² On the basis of these figures it also appeared that approximately 13 percent of the white children and 27 percent of the colored children under 1 year of age at the census date were not reported to the census enumerators. There are in addition considerable differences between States in the completeness of birth registration, the estimated proportion unrecorded ranging from 1 percent or less in Massachusetts, Connecticut, New Jersey, and Minnesota to over 15 percent in South Carolina, Georgia, Tennessee, and Arkansas. Although the information on these matters for years before 1940 is mostly indirect, it shows fairly conclusively that birth registration was less complete in 1930 and 1920 than at the present time. Much less is known of how the proportion of children reported to enumerators has varied in the past, but there are reasons for believing that here, too, there has been improvement.

The ratio of children to women for census years from 1800 to date shows clearly that the long-time trend of fertility in the United States has been downward and that a great decrease has occurred. In 1800 there were approximately 1,342 children under 5 for every 1,000 women age 20 to 44. The ratio continued to fall thereafter to 1,085 in 1840, to 780 in 1880, to 604 in 1920, and to 426 in 1940 (see table B 1). The last figure is less than half of that for 1860, and less than one-third that for the beginning of the nineteenth century. Actually the drop in fertility is greater than these figures indicate for during the period there has been a decrease of over 80 percent in infant and child

mortality. The ratios can be computed for Negroes from 1850 to date, and show that Negro fertility has dropped by more than 50 percent during this period, a decrease almost as great as that for white women.

As far back as the ratios go there have been large regional differences in fertility. In 1795-99 the fertility of white women was highest in the East North Central States (1,918), and lowest in New England (1,164). In 1935-39 it was highest in the East South Central States (559), and lowest in the Middle Atlantic States (339). In both instances the low regional ratio of children to women was almost exactly three-fifths of the high. In general each region has followed the same trend as the Nation as a whole, with the more urban and industrial regions leading the way and the more rural and agricultural regions following them with a lag of some 50 to 80 years. The Nation has usually been from 30 to 50 years behind the region with the lowest fertility. This lag has narrowed in recent years, however, for the low fertility level of the Pacific States during 1915-19 was reached by the national averages early in the 1930 decade.

A much more accurate idea of fertility trends since 1920 is given by birth rates by age of mother; that is, the number of births per thousand women aged 15-19, 20-24, and so on up to 45-49. Adding these rates and dividing by 10 gives the average number of children born to 100 women living up to age 50. Multiplying this figure by the percent of babies which are girls gives the gross reproduction rate, a convenient measure of fertility.

From the end of the demobilization after World War I to the worst year of the depression there was a large and almost uninterrupted drop in the gross reproduction rate. In 1921 the rate for native white women in the birth registration area was 139, while by 1933

² See section C for a discussion of assumptions with respect to the under-registration of births and of infant deaths and the under-enumeration of children. See also *Vital Statistics-Special Report*, Vol. 17, No. 18, April 1943.

¹ In an attempt to improve the comparability of white and Negro ratios, all ratios have been adjusted for under-enumeration, and all except those for whites in 1800 to 1820 have been standardized to the age distribution of United States women in 1930. The number of white children 0-4 enumerated has been increased by 5 percent, and of Negro children by 11 percent in the North, 13.5 percent in the South, 8 percent in the West, and 13 percent in the United States, these being factors obtained from a study of data for 1925-30.

² At the time of writing the white children under 5 in 1940 have not been distributed according to nativity of mother by the Bureau of the Census. However, the ratio for native white women 20-44 in 1940 should be only slightly less than that for all white women, because such a small proportion of the latter were foreign born. Ratios for divisions in 1940 are computed from preliminary data.

it was only 103 (see table B 2). If allowance is made for the addition of highly fertile States to the area during these years the decline is found to be at least 20 percent larger. Since 1933, however, there has been a reversal of this trend, the gross reproduction rate for 1941 being approximately 114 and that for 1942, 125. The latter figure is more than 20 percent above 1933, and higher than for any year since 1925.

*Registered births have been adjusted to allow for incomplete registration.

¹ Connecticut, Massachusetts, Michigan, Minnesota, New Hampshire, New York, Pennsylvania, Vermont, District of Columbia, Maryland, Indiana, Kansas, Kentucky, North Carolina, Ohio, Utah, Virginia, Washington, Wisconsin, California, Oregon, and Nebraska. ² Maine omitted because of lack of age data.

³ Rhode Island, Delaware, Mississippi, New Jersey, Illinois, Montana, Wyoming, Florida, Iowa, North Dakota, and West Virginia plus the States in note 1.

⁴ For method of estimating see "Population Statistics—State Data," National Resources Committee, Washington, G. P. O., October 1937.

Wide differences are found in the trends of the birth rates for native white women by 5-year groups within the childbearing period. Rates for the younger women (ages 15-29) did not decline as rapidly as those for the older women (ages 30-44) and rose more rapidly after 1933. In fact, during the last 5 years the fertility of those 15-19 was almost as high as during the early 1920's. In contrast the birth rates for women 30-34 did not stop declining until 1936, and those for women 35-39, and 40-44 were lowest in 1939 and 1941 respectively. The percentage change from 1921 to 1941 varied directly with age, women in the age group 15-19 bearing children at nearly the same rate in the latter year as in the former, but the rate for these aged 40-44 being cut to less than half.

*Registered births have been adjusted to allow for incomplete registration.

¹ Connecticut, Maine, Massachusetts, Michigan, Minnesota, New Hampshire, New York, Pennsylvania, Vermont, District of Columbia, Maryland, Indiana, Kansas, Kentucky, North Carolina, Ohio, Utah, Virginia, Washington, Wisconsin, California, Oregon, and Nebraska.

² Delaware, Mississippi, New Jersey, Illinois, Montana, Wyoming, Florida, Iowa, North Dakota, and West Virginia, plus the States in note 1. Rhode Island omitted because of lack of data on order of birth.

Data on order of birth show a corresponding divergence of trends. The rate for first births to native white women in the childbearing period dropped about one-third between 1921 and 1933, but by 1942 it had regained much of the loss (see table B 3). For second births the decline was somewhat smaller on a relative basis, as was also the subsequent recovery. For third, fourth, and later children, however, the decline continued longer and increased in relative size as order of birth rose. The downward trend of the rate for third births did not stop until 1937, for fourth births until 1939, and for higher birth orders may not have stopped even now. Moreover, births of fifth and subsequent children now occur at less than half the rate of 20 years ago.

Birth rates between 1920 and 1940 by age of mother can also be used to ascertain the average number of children ever born to women aged 35-39 or younger in 1940. For example, adding births in 1935 per hundred women aged 15, births in 1936 per 100 women aged 16, and so on up to 1939 will give the number of births prior to 1940 per hundred women aged 19-20 at the beginning of that year. Carrying out this process by age group shows that 100 women aged 35-39 in 1940 had borne approximately 23 children when they were between 15 and 20, 91 by the time they were 20-24,

TABLE B 4.—*Number of Live Births up to Specified Age to 100 Native White Women, by Age in 1940*¹

Age in 1940	Live births to 100 native white women up to age—				
	15-19	20-24	25-29	30-34	35-39
15-19	23				
20-24	21	88			
25-29	24	85	147		
30-34	23	90	147	189	
35-39	23	91	155	195	217

¹ Computed by the Scripps Foundation for Research in Population Problems from birth rates for the current birth registration area, adjusted for the incomplete recording of births. Because several States with high birth rates were not in the registration area during much of the 1920 decade, births to women 30-34 in 1940 probably are low by 1 to 10, and births to women 35-39 probably are low by 1 to 12.

155 by age 25-29, 195 by age 30-34, and 217 by age 35-39 (see table B 4). Because of the declining birth rates mentioned above, younger women have fallen somewhat behind the pace set by this older age group. Thus 100 women aged 25-29 in 1940 had borne a total of 147 children on the average, compared with 155 for the older women when they were in the same age group. Since the recent rise in birth rates has had little effect on those at ages over 30, it is probable that a similar comparison in 1945 would show wider differences between these two groups of women. The significance of these declines in fertility can be seen from the fact that with the present level of mortality 100 women living to age 50 must bear approximately 222 children if population numbers are to be maintained.³ The native white women who were aged 35 to 39 in 1940 will exceed this requirement slightly, but the younger women will fall below this fertility quota unless their birth rates rise substantially above those prevailing in 1940.

One reason that the average number of births to each 100 native white women aged 35-39 in 1940 was barely above the replacement level was the large proportion of the women who had borne no children or only one. Birth data by age of mother and order of birth for the period 1920 to 1940 show that approximately 27 percent of the native white women who were between the ages of 35 and 40 in 1940 had borne no children, 19 percent had borne only 1, 20 percent had borne 2, 13 percent had borne 3, 12 percent had borne 4 or 5, and only 9 percent had borne a larger number of children. Many of the childless women were unmarried, but even among the married women approximately 16 percent had never had a child (see table B 5).

Since 1920 regional differences in age-specific birth rates of native white women have resembled the corresponding differences in the ratios of children to women. In 1940 the highest birth rates for mothers aged 15-19 and 30-44 were to be found in the East

³ At present death rates a net reproduction rate of 100 requires a gross reproduction rate of 108, i. e. the birth of 108 girls to 100 women living through the childbearing period. With the present sex ratio at birth, 108 out of each 222 babies of native white mothers are girls.

TABLE B 5.—*Distribution of Native White Women Aged 35-39 in 1940 by Number of Children*¹

Marital status	Percent who had borne—						
	No children	1 child	2 children	3 children	4 or 5 children	6 or 7 children	8 or more children
All women	27	19	20	13	12	5	4
Married women	16	22	23	15	14	6	4

¹ Computed by the Scripps Foundation for Research in Population Problems from birth rates for the current birth registration area, adjusted for the incomplete recording of births. Because several States with high birth rates were not in the registration area during much of the 1920 decade, the percentages of women with "no" or "1" child are slightly high and with 4 or more children are slightly low. It is estimated that over 11 percent of the native white women 35-39 in 1940 had not been married up to that time.

South Central States. The highest rates for women in their twenties were in the Mountain States, though only slightly exceeding those for the East South Central section of the country. At the other extreme the lowest fertility rates for women aged 25 and over were in the Pacific Coast States. For women under 25, by far the lowest rates were to be found in New England and the Middle Atlantic States (see table B 6). A marked association is to be observed between high birth rates and rural areas, or, conversely, between low birth rates and urban areas.

The tendency has been for the more urban and industrialized States to lead in the decline of birth rates, and for the Nation to follow the same trend with a lag of several years. The birth rate for the United States in 1940 was of the same order as that of the Pacific States in 1919-21. For women age 20-34 the national trend

TABLE B 6.—*Number of Births per 1,000 Native White Women, by Age, and Gross Reproduction Rates, United States by Divisions, 1918-21, 1929-31 and 1940*¹

Division	Year	Births per 1,000 women aged—							Gross reproduction rates

¹ For 1918-21 and 1929-31 see "Population Statistics—State Data," National Resources Committee, Washington, G. P. O., October 1937.

has lagged from 10 to 20 years behind that for New England and the Middle Atlantic States. At older ages (35-44) the lag has been less than 10 years, while under age 20 it has been in excess of 20 years. If similar relations hold in the future, the downward trend of the national birth rate would bring it between 1950 and 1960 to the present level in New England and the Middle Atlantic States. The gross reproduction rate of native white women would then be approximately 80; in other words, 100 women living to age 50 would on the average have 165 children. To maintain a stationary population at 1950-60 death rates would require a gross reproduction rate of 105 to 107, or an average of 216 to 220 births to each 100 women living through the reproductive period.

Fertility trends in other countries

A marked decline of fertility is not peculiar to the United States, but has occurred in most of the countries of Western civilization. In some of them the birth rates began to decrease early in the nineteenth century; in nearly all the rates have fallen rapidly during the last 20 years. Accurate figures are not available for all countries and for all years, but those that are available show the downward trend in unmistakable terms.

³ White persons only.

⁴ From table B 2.

Italy, Poland, Portugal, and Bulgaria illustrate what has taken place in countries that still maintain a relatively high fertility. In Italy the gross reproduction rate declined from 200 in 1922 to 143 in 1935-37 (see table B 7). Information for Poland begins with 1927-28, at which time the gross reproduction rate was 195.

By 1933-36 it had fallen to 148. Reductions of much the same order occurred in Portugal and Bulgaria.

The declines have been correspondingly large in the countries which now have lower fertility. In Hungary the gross reproduction rate of 120 in 1937-38 was less than half the rate of 260 in 1900-01. In Australia the decline was from 168 in 1908-13 to 105 in 1932-36. Even in France, which is usually thought of as having had a low birth rate for many decades, there was a decrease from 145 in 1892-97 to 100 in 1935-36. The largest decrease occurred in Austria, from 248 in 1895-1900 to only 77 in 1935-36.

There was a post-depression increase of fertility in a few foreign countries as well as in the United States. In Sweden the gross reproduction rate declined from 215 in 1871-75 to 160 in 1911-15 and then to 82 in 1933-35, but rose slightly to 88 in 1938. Norway and Denmark displayed similar trends. In Germany a decline in the gross reproduction rate from 246 in 1881-90 to approximately 84 in 1930-33 was followed by a rise to approximately 112 in 1939-40. This rise in Germany may be attributable at least in part to the various measures adopted to increase family size, but in New Zealand, with no such program, a decrease of the gross reproduction rate from 154 in 1911-15 down to 102 in 1935-36 was followed by an increase to 129 in 1940.

To sum up the experience of other countries, a downward trend in fertility has been the almost universal rule. Upswings have rarely occurred during the years for which reliable records are available. Except for those upswings of short duration which followed World War I, they are limited to the recent post-depression gains in a few countries and to the increase which accompanied the onset of the present conflict.

The outlook for the birth rate in the United States

The situation with regard to the trends of fertility in the United States can be summarized from the foregoing account as follows.

Since the earliest period covered by vital records, around the beginning of the nineteenth century, there has been a steady decline of fertility in the United States as measured by the ratio of children under 5 to women in the childbearing age period. The fertility of Negroes, at least after 1850, seems to have followed a parallel course.

Fertility has declined throughout the United States, but there have continued to be wide regional differences. In recent years the fertility of white women has been highest in the East South Central States, lowest in the Middle Atlantic States.

The downward trend of fertility appeared first in the more urban and industrial sections of the Nation, but the rural and agricultural areas have followed the same trend, though with a lag of some 50 to 80 years.

The downward trend of fertility has been greater than average among women of 30 and over, and less than average among women 15 to 30, resulting in a greater concentration of childbearing at the earlier ages.

It remains to be seen what are the implications of these observations for the future course of fertility in the United States. If the long-time trends were to be followed, the birth rate of the country would soon be carried well below the replacement level. Fortunately, however, events of the past few years have given evidence that fertility trends are not irreversible, for as noted above there has been a definite upturn since 1933 and a sharp if perhaps only temporary rise with the onset of war. This upturn during the past decade may eventually prove to be no more than an interruption of the trend, but nevertheless it serves to indicate that the observed movements of fertility must be interpreted with reference to their underlying causes, not simply their direction of change.

Without attempting to summarize the evidence, it can be concluded that the decline in fertility that has occurred in the past is not due to any biological change such as an increase in the incidence of sterility or a reduction in the capacity for childbearing.⁴ The indication is that complete sterility does not occur in more than 8 or 9 percent of the white couples in the population as a whole, a frequency much too low to account for any considerable part of the great decrease of fertility that has occurred. Comparison of groups of high and of low fertility does not reveal any innate difference in childbearing capacity.

The theory has been advanced that an increase in the number of induced abortions has been an important contributory cause of the decline of births. Without attempting to minimize the serious effects of such interruptions of pregnancy, it may be said that what little information is available indicates that these do not occur with sufficient frequency to account for a major reduction in the birth rate, and that there has been no demonstrable increase in their frequency in recent decades.

Another factor to be dismissed in like fashion is that of accidents of pregnancy. The effect of advances in prenatal care, in fact, has been such as to tend to raise rather than to lower the birth rate, by reducing the amount of pregnancy wastage. While it is true, as mentioned above, that little reduction has been effected in neonatal mortality from congenital malformations

⁴ See Pearl, Raymond: *The Natural History of Population*, New York, Oxford University Press, 1939, p. 334, for material bearing on the conclusion that there has been no significant change in childbearing capacity for a century or more. Evidence that sterility is not sufficiently prevalent to account for the decline of the birth rate in recent decades is given by as yet unpublished data of the Indianapolis study of the Committee on the Social and Psychological Factors Affecting Fertility. This study is sponsored by the Milbank Memorial Fund, with the support of the Carnegie Corporation of America. Members of the committee are Lowell J. Reed, Daniel Katz, E. Lowell Kelly, Clyde V. Kiser, Frank Lorimer, Frank W. Notestein, Fredrick Osborn, S. A. Switzer, Warren S. Thompson, and P. K. Whelpton.

and premature birth, it is undoubtedly true that improvements in maternal care and nutrition have made it possible to bring a larger proportion of all conceptions to term than was formerly the case.

¹ Taken from current census volumes.

Another possible cause of the decline in the rate of births to native white women in the United States is a less favorable pattern of marriage, such as a decrease in the proportion of persons who marry or a postponement of marriage until later years of life. Census data indicate, however, that no such unfavorable developments occurred from 1890 to 1930 (see table B 8). During this period there was a substantial increase in the proportion married among native white males in their twenties and among native white females under age 30, and to a lesser extent the same was true for higher age groups. In short, the trend during these decades was toward a lower average age at first marriage and a higher proportion of persons marrying before middle age. Such changes had the tendency to increase birth rates rather than to lower them.

Estimates of the number of marriages in each year since 1910, made by the Bureau of the Census, show that large fluctuations occurred at certain periods. During the first World War the marriage rate⁵ declined to a low of 83 in 1918, the year the army was largest, then rose to a high of 104 in 1920 immediately after demobilization (see table B 9). During the prosperous decade of the 1920's the marriage rate fluctuated between 86 and 97, the general trend being slightly downward. During the first part of the depression (1930-32) the rate fell rapidly, reaching a low point of 69 in 1932, after which it returned to 96 in 1937 as economic conditions improved. From 1939-41 there was another sharp rise, presumably due to general economic improvement and the imminence of war. The 1941 marriage rate of nearly 109 was well above

⁵ The term "marriage rate" as used here refers to the number of marriages per 1,000 women aged 17 to 29, inclusive, this being the age range within which most women marry.

the highest known for any preceding year, but may have been surpassed in 1942.

If there had been no depression and recovery during the 1930's it is probable that the marriage rate would have continued about as it was during 1925 to 1929. The number of marriages that would have occurred each year under such conditions is shown in the column "Expected Marriages" of table B 9, and represents

1941	108.7	1,679	1,376	-303	107

¹ The number of marriages per 1,000 women aged 17 to 29, inclusive. This age period is used as a base because it contained over 75 percent of all the women marrying in the marriage registration area in 1939 and 1940, and a substantially higher percent of the women marrying for the first time.

² From Vital Statistics—Special Reports, Bureau of the Census, Vol. 15, No. 13, p. 141, (Feb. 20, 1942).

³ Computed on the basis that the marriage rate for each year from 1930 to 1941 would equal the average rate for 1925-29, i. e., 89.1.

⁴ The number of marriages expected minus the actual number.

⁵ The sum of the annual deficit up to and including the year specified.

what might be called the normal trend. The depression reduced marriages far below normal in each year from 1930 to 1933, the maximum "deficit" being 290,000 in 1932. By the end of 1933 the cumulative "deficit" of marriages amounted to 62.1 percent of a year's quota. Since 1934, however, the actual number of marriages has exceeded the "expected" number in every year except 1938, and the "deficit" has almost been wiped out. This does not prove that all the people who postponed marriage during the depression years have now married. On the contrary, it is probable that a considerable number will never marry, or will not do so for several years to come. Offsetting this group of postponements, however, are younger persons who were able to marry sooner because of earlier and more profitable employment or who moved

their marriage dates ahead for reasons connected with the entrance of the United States into the war.

The year-to-year fluctuations in the marriage rate since 1929 help greatly in explaining the changes in birth rates during the same period, particularly in the rates for first and second children. There is a strong tendency for a couple to have their first child within 2 or 3 years after marriage, and their second child within another 2 or 3 years. In view of this time relation it is surprising that the drop in the marriage rate from 1929 to 1932 and the rise thereafter did not cause a larger drop in the rate of births of first children between 1930 and 1933, followed by a larger rise in subsequent years. Similarly these fluctuations in the marriage rate were large enough to have caused greater changes in the rate of births of second children the appropriate number of years later. In other words, the rise in the birth rate for first, second, and even third children which occurred in recent years could easily have resulted from changes in the marriage rate caused by the depression, the recovery, and the preparations for war. In view of this fact it is premature to say that the rise in the gross reproduction rate since 1933 indicates that the long-time downward trend in fertility has been permanently reversed, or even permanently checked. Such a conclusion must be postponed until the marriage rate is no longer inflated by the consummation of marriages that were postponed because of the depression or moved ahead because of an improvement of income or the imminence of war.

As stated above, there is reason to believe that little if any of the long-time decline of the birth rate in the United States can be attributed to a biological change in the fecundity of women, to an increase in the amount of sterility, to more induced abortions and accidents of pregnancy, or to an increasingly unfavorable pattern of marriage. This leads to the conclusion that the long continued and general reduction of the birth rate has been effected through a wider practice and an intensification of voluntary limitation of family size. The evidence in support of this conclusion, it may be said, is not only of the negative sort indicated above, but is also positive in character.⁶ If the immediate explanation of the downward trend of fertility lies in this direction, as seems probable, then the future course of the birth rate will depend on (1) further dissemination of

⁶ There is known for example to have been a considerable increase in the sale of contraceptives and an advance in the efficiency of certain of the materials. In addition, a number of studies of special groups have shown that the control of fertility is widely practiced, with considerable effect on family size. See for example Pearl, Raymond, *The Natural History of Population*, New York, Oxford University Press, 1939; Stix, Regine K. and Notestein, Frank W., *Controlled Fertility*, Baltimore, Williams & Wilkins Co., 1940; Beebe, Gilbert W., *Contraception and Fertility in the Southern Appalachians*, National Committee on Maternal Health, Baltimore, Williams & Wilkins Co., 1942. Confirmatory evidence is given by unpublished data from the Indianapolis study of the Committee on the Social and Psychological Factors Affecting Fertility, which demonstrate an inverse relation of family size to the degree of control exercised over fertility.

the pattern of control, (2) changes in the number of children that couples wish to have, and (3) changes in the strength of the inducements to hold family size within this number.

It can probably be taken for granted that insofar as the first of these factors is concerned, the tendency will be toward a more widespread adoption of the concept of family limitation. Incident upon the war, great shifts of population are taking place from one section of the United States to another. Numbers of men are entering the armed forces, workers and their families are going to defense industry, and people from areas of traditionally high fertility are coming in contact with new ways of life. A wider dissemination of knowledge of effective control measures is therefore to be expected.

Less can be said of what will in the future come to be considered the optimum size of family, and of the nature and strength of the inducements to attain but not exceed this number. It can be seen that both will depend very directly on the nature of the post-war world and on the kind of lives that people are able to lead. On the success with which solutions are found for the international problems of security and the domestic problems of economic readjustment after the war will depend the willingness of people to undertake the responsibilities of marriage and childbearing, the age at which they are able to marry, and the number of children they wish to have. The future birth rate in the United States will certainly be influenced also by the internal migration that is both under way at the present time and in prospect at the end of the war, for these movements disturb the local proportions between the sexes, take people from areas of high to those of low birth rates, and expose many persons to new ideas and new ways of life. Thought and behavior with respect to reproduction will be still further affected if additional services and allowances come to be provided for families with young children.

Hypothetical fertility trends, 1940 to 2000

When all of these matters are taken into account there remains little justification for estimating the future trend of the birth rate by the extrapolation of any curve fitted mathematically to the rates of earlier years. Most mathematical extrapolations of past trends in the birth rate of the native white population would give values for the year 2000 that seem absurdly low, being less than a hundred births for each hundred women living through the childbearing period. Such declines would assume a considerable increase in the proportion of married couples controlling the size of their families and a marked decrease in the number of children that they wanted. The result would be that the couples having no children or only one would out-

number those with two or more. Such a situation is considered improbable. It seems more probable that the proportion of married couples wanting two or three children will remain sufficiently high to prevent such large declines in the average number of children per family and to maintain an average of at least 150 births per hundred women living to age 50. This figure is taken as the low fertility assumption. It sets the gross reproduction rate for 2000 at 73, the same as that for the District of Columbia in 1940, but below the lowest state rate for that year (78 in New Jersey). Since a gross reproduction rate of 103 to 105 will be needed to maintain a stationary population with the expected death rates in the year 2000, low fertility would bring about a decreasing population, unless offset by immigration.

On the other hand, it seems unlikely that the causes underlying the long-continued decline of the birth rate will undergo any radical change. At best, then, the conditions favoring higher birth rates can be expected to do no more than offset the tendency toward further decline. In effect this is to assume that the expected increases in the proportion of couples controlling the size of their families will be counterbalanced by some increase in the average number of children wanted. The high fertility assumption, taken on these grounds, is that the gross reproduction rate of the native white population will remain horizontal, fluctuating about the 1940-42 value of approximately 113. Since this exceeds the replacement level of reproduction, the high fertility assumption provides for a continued natural increase of the population.

The high and low assumptions are designed as extreme values. More probable, insofar as the immediate future can be anticipated, is a course of fertility somewhere between these extremes. The medium assumption is in effect that there will be a moderate increase in the proportion of married couples restricting the size of their families, and that there will be little change in the number of children that they want. Under these conditions the long-time downward trend in fertility will continue during the next 60 years, but the rate of decline will be retarded substantially. Under the medium assumption for the birth rate in the year 2000, 100 native white women living through the childbearing period will bear 190 children, and the gross reproduction rate will be approximately 92. This brings the national gross reproduction rate of the native whites to the 1940 level of the New England States, well below the rate required for the maintenance of a stationary population. Consequently the medium as well as the low fertility assumptions lead eventually to a decreasing population unless offset by sufficient immigration from abroad.

In setting the high, medium, and low assumptions

for the native white birth rates in 2000, allowance was made for differences in the fertility trends at the various age levels. Thus, in the low assumptions the rate of decline from 1940 to 2000 is greatest for women in the latter part of the childbearing period, and least for those in the first part. Similarly, in the high assumptions there is an increase in the birth rates of women aged 15-34, but a decrease in the rates for women aged 35-49. In all assumptions the effect is to continue the concentration of reproduction in the age period 20-29 (see table B 10).

TABLE B 10.—*Birth Rates and Ratio of Children to Native White Women in the United States, 1940 to 2000*

BIRTHS PER 1,000 NATIVE WHITE WOMEN

Age period	1940	High assumptions				Percent change 1940-2000	Medium assumptions				Percent change 1940-2000	Low assumptions				Percent change 1940-2000

¹ Standardized to the age distribution of all United States women in 1930.

The high, medium, and low rates having been determined for each age level in 2000, rates for the years between 1940 and 2000 were obtained by interpolation along a smoothed curve. In nearly all cases it was assumed that the rate of change would decrease gradually, but in sufficient degree to bring the 1995 birth rates very close to those for 2000, and to make the trend line nearly horizontal thereafter. The resulting trends at each age for the three assumptions are shown in figure 2. The long-time trend in the ratio of children to women is shown in figure 3.

Fertility trends assumed for foreign-born white women and for Negro women were based on those for native white women. During recent years the birth rates of foreign-born white women have been decreasing faster than those of native white women. It is expected that the forces narrowing the differential in the past will continue to operate in the future. Birth rates of colored women declined more rapidly than those of native white women from 1905-9 to 1915-19, and less rapidly from 1925-29 to 1935-39. Since the limitation of family size is not yet as general in the colored population as among native whites, there is more prospect for its extension in the colored group. The result would be a more marked decrease in the birth rates of the colored population than in the rates of the native whites. Under the medium assumption, the relative

FIGURE 2.—Births per thousand native white women by age. Actual 1920 to 1940, estimated 1945 to 2000 under the assumptions of high, medium, and low fertility.

excess of the birth rates of the foreign-born whites and the colored over those of native white women is reduced by five-eighths between 1940 and 2000. Under the high assumptions, the percentage differential is reduced by one-half; in the low assumptions, by three-fourths.

Because birth rates are much more variable and more subject to individual control than death rates, the actual birth rates of future years can be expected to depart more widely from the medium assumptions than the actual death rates. Because the range between the high and low assumptions is much larger for birth rates than for death rates,⁷ however, the probability that the actual rates will fall between these extremes appears about as great for one as the other.

It is realized that it may be desirable in some instances to ascertain the effect on future population growth of birth rate trends other than the high, medium, or low assumptions. It is believed that this can be done with sufficient accuracy for most purposes by interpolation or extrapolation of the differences between the results based on these three series.

⁷ If the medium mortality trend is followed, the estimated population for the year 2000 ranges from 133,553,000 with low fertility to 190,694,000 with high fertility. This difference of 57,141,000 between the high and low fertility trends with constant mortality is nearly 5 times the difference of 12,492,000 between the high and low mortality trends with constant fertility.

C. UNDERENUMERATION OF CHILDREN

After the fertility and mortality assumptions have been made for the period 1940 to 2000, it is necessary to know the number of persons to which these rates are expected to apply. The most recent census is obviously the best source of such information. As mentioned above in section B, however, there is a tendency in the United States as in other countries for the persons seen by the enumerators to fail to report a certain number of children under 5 years of age. It is desirable, therefore, to make allowance for the children not counted in 1940 before estimating the future population.

With the information now available, the best method of estimating the number of children under age 5 who were not enumerated is to take the number of births registered during the 5 years ending on the census date, subtract the deaths of these children which occurred prior to the census date, and compare the remainder thus obtained with the census total for the under-5 age group. Greater accuracy is given by this method if allowance is made for unregistered births and deaths. According to a study made by the Bureau of the Census, 94 percent of the white births and 82 percent of the colored births which occurred from December 1, 1939, to March 31, 1940, were registered. Equally reliable information is not available for prior years but there are indications that birth registration gradually improved in completeness from 1935 to 1940. Less is known about

FIGURE 3.—Number of children under five years of age per thousand white women 20–44 years of age. Actual 1800 to 1940, estimated 1945 to 2000 under the assumptions of high, medium, and low fertility.

the proportion of deaths of children under age 5 that remained unregistered, but there are reasons for believing that death registration has been nearer completeness than birth registration.

In the present report it is assumed that 93.6 percent of the white births and 81.6 percent of the colored births occurring from April 1, 1935 to March 31, 1940, were registered and that 96.8 percent of white deaths and 90.8 percent of the colored deaths in this group were registered.^{7a} On this basis 6.6 percent of the native white boys and 6.1 percent of the native white girls under 5 years of age on April 1, 1940, were not reported to the census enumerators. For the colored children under 5 the percentages are 16 for boys and 14.5 for girls. In other words, the number of children under 5 on April 1, 1940, is assumed to be the number reported by the census increased by the following percentages: native white boys, 7.1 percent; native white girls, 6.5 percent; colored boys, 19.0 percent; colored girls, 16.9 percent.

Two estimates of the number of children under 5 years of age are given in each table of future population (tables 2 to 13 inclusive), one in the body of the table and one in a separate line beneath. The larger number, given at the bottom of each table, represents the

^{7a} The percent of child deaths not registered is assumed to be half the percent of births not registered.

estimated total number of children aged 0-4 and is indicated to have been "adjusted for under-enumeration of children by census." The smaller number, included in the body of each table, was obtained by decreasing the full estimate of the number of children under 5 in the proportion that such children were estimated to have been missed in the 1940 census. It is this figure and the accompanying population total that should be compared with census data for 1940 and other years.

There is evidence that the 1940 census, like those of other years and other countries, contained certain other discrepancies. For example, it appears that an appreciable number of young men, aged 18 to 25 or thereabouts, were omitted from the census because they were

"on the move" at the time of the enumeration. Since there is little basis for estimating the size of this group, no adjustment has been made for it in this report. It is also apparent that the 1940 census figures for the age groups 60-64 and 65-69 are somewhat in error, an important proportion of the persons immediately under 65 having been reported to the enumerators as 65 or older. The most probable explanation is that such persons believed that the greater their reported age on the census schedules the earlier they could obtain benefits under the Social Security program. In any event, an adequate basis for estimating this error is not available, and no attempt has been made to correct the census figures in these age groups.

D. IMMIGRATION AND FUTURE POPULATION GROWTH

Immigration to the United States has in the past been a major factor in shaping the size and composition of the country's population, but in recent years the volume of immigration has come to be sharply curtailed by regulation and by unsettled economic and political conditions. The demographic effects of earlier migration continue to be felt in the form of an upward movement of the large body of foreign-born into the higher age groups, but within a few decades this group will largely disappear unless recruited by new immigration (see fig. 4). It remains to be seen if domestic opinion in the United States and international conditions after the war will again permit a resumption of heavy immigration. It may be assumed that there will continue to be large numbers of persons desirous of taking residence in this country, but until such time as national policy with respect to the admission of aliens after the war has been determined, no estimates can be made of the future volume of immigration. It is possible, however, to estimate the approximate effect on the size and composition of the population of the United States of an arbitrarily assumed volume of immigration. From this specimen projection of population trends, the demographic effects of larger or smaller amounts of immigration can be inferred.

From past experience it is clear that unless immigration is prohibited in the years to come its volume will vary widely from year to year, depending on economic and political conditions here and abroad. For the purpose of estimates of future population, however, it is necessary to assume some average rate of entrance of aliens to this country. The assumption made for this report was that immigration would not begin until 1945, and that at the end of each succeeding 5-year period there would be 500,000 foreign-born persons resident in the United States who had entered during that interval. This rate of immigration corresponds to

about two-thirds of the present over-all quota limit.

Three sets of estimates of future population were prepared with allowance for immigration at the above rate, based on the assumption of medium mortality in combination with high, medium, and low fertility. (see tables 4, 8, and 12). The sex and age distribution of the new immigrants was taken to be that of those arriving during the period 1925 to 1929, the most recent years for which there was any considerable volume of immigration. For a 5-year period this distribution is as follows:

Distribution of 500,000 Foreign-born White Immigrants

[Thousands]

Age	Male	Female	Age	Male	Female
0-4.....	5.6	4.0	50-54.....	.6	5.1
5-9.....	13.9	8.9	55-59.....	.4	4.0
10-14.....	21.4	14.0	60-64.....	.2	2.6
15-19.....	38.1	26.1	65-69.....		1.5
20-24.....	94.1	54.6	70-74.....		.9
25-29.....	73.4	46.0	75-79.....		.5
30-34.....	30.9	24.8	80-84.....		.4
35-39.....	2.6	14.6	85-89.....		.4
40-44.....	-4.6	9.7			
45-49.....	-1.6	6.9	Total.....	275.0	235.0

It is to be noted that a net emigration of males is assumed for the age groups 40-44 and 45-49, an outward movement having occurred at this age level in the base period of 1925 to 1929.

The birth rates and death rates applied to the new immigrants were those for the foreign-born white population. Their American-born children, however, were assumed to be subject to the birth rates and death rates of the native white population. Any marked changes in immigration policy leading to the entry of large numbers of aliens having birth rates and death rates different than those of the foreign-born now in this country would, of course, make necessary a revision of these calculations.

E. THE DISTRIBUTION OF WAR LOSSES

As related to the estimation of future population, immigration and war losses present similar methodological problems, for while it is clear that both will directly affect the size and composition of the population of the United States, there is at present little basis for the estimation of their future amount and effects. For this reason the procedure that was followed in dealing with the problem of war losses, parallel to that for immigration, was to prepare a reasonable but hypothetical age distribution for war losses, and to provide materials for the revision of the estimates of future population when the full toll of casualties is known.

War affects population trends in two ways, first through an increase in deaths, secondly through changes in the number and the timing of births. Wartime mortality might be defined to include only the casualties resulting directly from military action, or might be broadly interpreted to include deaths in the civilian population resulting indirectly from the war, such as those attributable to industrial accidents, longer hours of employment, or lowered standards of medical care. If direct casualties only were taken, estimates of the sex and age distribution of wartime deaths would be very different for countries subject to the bombing of civilian centers than if losses were presumably confined to the armed forces. In the latter case the distribution of military losses would depend on the age composition of the armed forces as set by recruiting and induction policy, on the types of military operations, and on the duration of the conflict.

It is obvious from these considerations that only a rough estimate of the age distribution of war losses can be made, but some estimate is nevertheless needed. The procedure followed was to deal only with military losses and to base the estimate of their age distribution on experience in the previous war. Data for Germany and England and Wales were employed as providing the most extensive information. The distribution so obtained was as follows:

Age group	Percent of all war losses	Age group	Percent of all war losses
17-21.....	22.38	32-36.....	13.80
22-26.....	33.94	37-41.....	6.72
27-31.....	21.13	42-46.....	2.03

Military losses in excess of age 46 were so small as to be negligible. These percentages were then used to distribute a unit number of losses, the units that were used being 100,000 native white males and 10,000 colored males. The distribution so obtained was then projected forward under medium mortality and three fertility

assumptions to provide a series of correction tables which could be adjusted by an appropriate fraction or multiple when the final casualty totals were known, then applied in revision of the estimates of future population (see tables 15, 17, and 19).

Included in the same war loss correction tables was allowance for the eventual reduction in the number of births because of the smaller number of potential parents after the war. The procedure followed here was, in brief, to translate the unit losses into percentage losses in the corresponding age groups of males, reduce these percentages to allow for the proportion remaining single up to age 55, and then use the reduced percentages to decrease the birth rates for females in the corresponding age groups. On the basis of the unit number of war losses, the following percentages of normal birth rates were obtained for native white women of the indicated ages.

Age group	Percent of normal birth rate	Age group	Percent of normal birth rate
15-19.....	99.614	30-34.....	99.829
20-24.....	99.440	35-39.....	99.929
25-29.....	99.687	40-44.....	99.979

A similar procedure was followed for the revision of the estimates of colored fertility. Larger or smaller war losses would of course affect the birth rates proportionately. Since the war loss correction tables are in terms of absolute numbers, a direct numerical adjustment to the eventual number of losses can be used throughout.

The computation of the effect of war losses was carried on to the end of the century in the correction tables, and therefore secondary effects were set up as the wartime and post-war reduction of births came to affect the second post-war generation. Because of this cumulative effect an initial loss of 110,000 during the war would be increased to 300,000 by the year 2000 under the medium assumptions of fertility and mortality. High fertility would increase this to about 370,000 while low fertility would reduce it to about 240,000.

In addition to the military losses during the war and the consequent change in the size of the succeeding generations, another series of demographic repercussions will be set up by the disturbance of the course of the birth rate during the war period. The onset of the present conflict has been accompanied by a sharp rise in the marriage rate and the birth rate. Another increase in both rates may be expected to follow the termination of the war. Intervening between these two periods of high reproduction there may be an interval in which the rates fall below the pre-war trend, the

extent of the deficit of births depending among other things on the percent of the male population in the armed forces, practice with respect to the granting of furloughs to men in the service, and the course of the conflict. In this respect the long-term effect on the birth rate will depend quite as much on the duration of the war, that is, on the length of the interval separating the initial and the post-war peaks of reproduction, as on its intensity as measured in terms of military losses. A war of short duration might well give a net increase of births over the war and immediate post-war period, the initial and subsequent rise of births more than canceling out any intervening deficit. Since it is not unlikely, however, that an actual deficit of births will occur before the end of the war, a second set of correction tables has been prepared to allow for a wartime reduction in the number of births. In form, these tables correspond to the war loss correction tables, and are designed to be applied in the revision after the war of the estimates of future population, taking into account the wartime reduction in the number of births. As before, the units are 100,000 for the native white population, 10,000 for the colored. Three sets of corrections are given, for the high, medium, and low fertility assumptions, respectively, coupled with medium mortality (see tables 14, 16, and 18).

Some care must be exercised in the application of these correction tables for birth reduction. For one thing, a fall of the birth rate below the inflated level of 1942 will not necessarily constitute a deficit of births, but may be merely a return toward a more normal figure. A deficit of births is to be distinguished from a

postponement of births, for the postponement of a number of marriages and births until after the war would merely introduce some irregularity into the age distribution of the population without necessarily having any permanent effect on the trend of total numbers. In effect, then, a wartime deficit of births cannot be measured until well into the post-war period, at which time it can be seen to what extent any eventual decline of births in the late stages of the war has been compensated by the higher fertility at the beginning of the war and in the immediate post-war period. For the purpose of the estimates of future population, a wartime deficit of births is to be measured against the levels of fertility set by the high, medium, and low-fertility assumptions. Under the three combinations of fertility and mortality assumed in tables 14, 16, and 18, the estimated average number of births per annum is as follows (in thousands).

Medium mortality	1940-44			1945-49		
	Total	White	Colored	Total	White	Colored
High Fertility	2,719	2,340	379	2,755	2,373	382
Medium Fertility . . .	2,684	2,310	374	2,621	2,258	363
Low Fertility	2,649	2,280	369	2,499	2,153	346

The wartime deficit of births is assumed to take place in 1944 and 1945. Since the fertility in 1945 may well be closer to that of 1944 than to the average figure for the later years, it is believed that the 1940-44 estimated average number of births may safely be used as the estimate for the year 1945.

INDICATED POPULATION CHANGES

F. GROWTH OF TOTAL POPULATION

The population of continental United States has for some time been growing more and more slowly. The decennial rate of increase, which was above 30 percent for the greater part of the nineteenth century, fell to approximately 20 percent around 1900, and was only slightly above 7 percent for the most recent intercensal period, 1930 to 1940. Under the current trends of fertility and mortality, the outlook, unless heavy immigration is resumed, is for a low rate of increase during the next few decades, with perhaps an eventual stabilization or even decrease of numbers. According to the medium assumptions of fertility and mortality, the population of the country would grow without the aid of immigration to about 151 million in 1960, this being a gain of some 20 million, or about 15 percent over the 1940 census figure. Under the same series of estimates a gain of only about 9 million is anticipated for the interval from 1960 to 1980. Soon after this time the favorable age composition carried over from the earlier period of higher birth rates will have spent its influence, and a decline of numbers is anticipated after 1985 (see table F 1).

Divergent trends of total population are given by the alternative assumptions of fertility and mortality (see fig. 5). The high fertility assumption gives a continued upward trend of numbers to the end of the century, the figure reached at a given time depending on the level of mortality that is assumed. For the year 2000 the high fertility assumption gives estimates ranging from 185 to 199 million, depending on whether a high, medium, or low level of mortality is used in the projection. With medium or low fertility, the curve of estimated total population continues upward for a time, but eventually turns down, regardless of what mortality is assumed. Under the assumption of medium fertility and low mortality, the maximum population is almost 168 million in 1990. At the other extreme, low fertility and high mortality give a maximum of less than 149 million in 1970, followed by a rather rapid decrease of numbers.

It is to be noted that this prospect of an eventual cessation of population growth is inherent in the present age structure and fertility rates of the population of the

United States. The present age structure, with a large proportion of the population in the middle range of years, is favorable to a continuance of an excess of births over deaths, but with the inevitable ageing of the population the balance will tip in the opposite direction, a large proportion of elderly people tending to give an excess of deaths over births unless a high level of fertility is maintained.

The above figures include no allowance for immigration. The effect of an inflow of foreign-born averaging 100,000 per annum beginning in 1945 is shown by three series of estimates included in table F 1. Under the medium assumptions, immigration at this rate would add about 1.7 million to the population by 1960, over 4.4 million by 1980, and over 7.2 million by the year 2000, a considerable portion of the latter totals being the American-born children of the immigrants. The allowance for immigration, however, does not greatly alter the shape of the curves of estimated popu-

¹ Average net immigration per annum, beginning in 1945.

lation, giving only higher totals and postponing somewhat the date of the population maxima. Immigration averaging 100,000 per annum would not be sufficient to prevent the eventual downward turn of numbers with medium or low fertility. A different effect

would, of course, be produced if the fertility pattern of the new immigrants departed widely from that of the present foreign-born population. Reference to the effect of war on population trends is made below.⁸

⁸ See section J.

TOTAL POPULATION OF THE UNITED STATES 1900-2000

FIGURE 5.—Trend of the total population. Actual 1900 to 1940, estimated 1950 to 2000 under alternative assumptions of fertility and mortality.

G. THE SEX RATIO

Accompanying the indicated trends of total population, marked changes in the proportion between the sexes are in prospect. In the past the sex ratio of the population of the United States, expressed as the average number of males per hundred females, has been largely determined by three major factors, these being

the greater number of males at birth, the lower mortality rates of females, and the high proportion of males among immigrants. Largely because of the latter factor, the United States has long maintained a relatively high sex ratio, attaining a maximum of 106 in 1910 at which time the census enumerated nearly

2,700,000 more males than females. Of this male surplus, approximately two-thirds was contributed by the foreign-born. With the subsequent decline of immigration, the decreasing proportion of children, and the gradual ageing of the population, the sex ratio has been slowly reduced, falling to 102.5 in 1930 and to a record low of 100.7 in 1940, at which time the recorded surplus of males was only about 450,000.

The near-term outlook, without allowance for immigration or war losses, is for a continuation of this downward trend of the sex ratio and for a future population containing somewhat more than 50 percent of females. Under the medium assumptions of fertility and mortality, the point of numerical equality between the sexes would be reached soon after 1945. Thereafter the sex ratio would continue downward under the influence of a diminishing proportion of foreign-born in the population, a diminishing proportion of children, and a high proportion of the population in the upper age groups, to reach a low point of 98.9 between 1965 and 1970. Beyond this point a slow rise of the sex ratio is predicted under the medium assumptions, with a balance between the males and females being regained in 1995. The reason for this eventual return to an equal or superior number of males is to be found in the mortality assumptions. Since the neonatal mortality of male infants is greater than that of females, the effect of the lowered infant death rates assumed in the medium mortality series is to increase the proportion of males in the lower age groups. This increase of the sex ratio in the first years of life, together with the lowered mortality rates provided for during childhood and early adult life,

means that the initial surplus of males would be carried on into higher age groups, eventually balancing the surplus of females at the upper ages. This tendency is demonstrated by the sex ratio of the estimated population at different age levels. According to the 1940 census tabulations the sex ratio, which began at 103.2 for the first 5 years of life, fell steadily in the succeeding age groups until the figure of 100 or equality in the numbers of males and females was attained for the age group 15-19. According to the medium assumptions this point of equality advances to age 20-24 in 1945, to age 25-29 in 1950, and to age 35-39 in 1960. By the year 2000 the initial surplus of males at birth would not be eliminated by their higher mortality until the age group 55-59 (see table G 1).

As the above review indicates, the future course of the sex ratio is directly a function of the male and female differential of mortality. Under the assumption of high mortality the outlook is for a continued surplus of females in the total population after about 1950. Under the low mortality assumption a slight surplus of females would appear around 1950 but would persist until only about 1980 or 1985, after which time a surplus of males would again be the rule.

Extensive immigration would raise the proportion of males in the total population if the selective factors in international migration continued to operate as in the past. The hypothetical rate of approximately 100,000 immigrants per annum, however, would produce only fractional changes in the sex ratio of the total population. Its effects would of course be most marked at certain age levels, notably in the early adult ages.

³ Estimates based on medium fertility and medium mortality.

H. AGE COMPOSITION

Of more immediate significance than the changing rate of population growth are the changes in the age structure of the population that are now under way. As compared to many other countries, the United States has long possessed a relatively youthful population and a high fraction of its inhabitants in the younger employable ages. It is recognized, however, that this age structure has been undergoing a change, with a gradual increase in both the number and the proportion of the population in the upper age groups. The immediate reasons for this shift toward the older ages are several in number. For one thing, the steady decrease in the birth rate over a considerable period of years has had the effect of moving upward the average age of the population. The falling off of immigration has had the same effect, there no longer being the strong influx of people for the most part in early adult life. At the same time the large body of foreign-born who arrived earlier has been moving up into the higher ages. In addition these tendencies toward an older population have been strongly reenforced by the lowering of the death rates during the early and middle years of life, enabling a larger proportion of the population to survive to later life. Since most of these tendencies will presumably continue for some time to come, the outlook is for a continuance of the trend toward an older population.

The rate at which this process of ageing of the population goes on will depend on the present age structure as well as on future birth rates and death rates. A resumption of the downward trend of the birth rate would have the effect of accelerating the trend toward an older population by further reducing the number of children, while a higher level of fertility would serve to maintain a more youthful population.

Median age

The trend toward an older population is shown by the change in the median age of the population, the central age above which and below which there are equal numbers of people. In 1800 half of the entire population of the United States was 16 years of age or younger. A century later the median age had risen to almost 23 years, and by 1940 it had reached a new high of 29. A further rise of the median age of the population is in prospect, the medium assumptions for fertility and mortality giving an estimate somewhat in excess of 37 years at the end of the present century. A high level of fertility in combination with medium mortality would reduce this figure by between 4 and 5 years, while a low level of fertility would raise it to 42. The outlook is in any event for a considerable increase in the median age of the population (see fig. 6).

FIGURE 6.—Trend of the median age of the total population. Actual 1800 to 1940, estimated 1950 to 2000 under alternative assumptions of fertility and mortality.

Population age 65 and over

The age distribution of the estimated future population by broad age groups and under two sets of assumptions is given in table H 1 (see also tables 7 and 11). According to these estimates the central age groups, 20-64, will remain quite stable in total numbers, although with a shift toward the upper age limit, but marked changes will take place in the highest and lowest age groups. Particularly marked is the expected increase in the number of persons 65 years of age and over.

Figures 7 and 8 show the trend from 1870 to 1940 in the number and percent of the total population aged

65 and over, together with hypothetical trends up to the end of the century. The number of persons enumerated in this age group has risen steadily from approximately 1,150,000 in 1870 to slightly over 3 million in 1900, almost 5 million in 1920, and over 9

FIGURE 8.—Trend of the percent of the total population aged 65 and over. Actual 1870 to 1940, estimated 1950 to 2000 under alternative assumptions of fertility and mortality.

I. COLOR AND NATIVITY

The estimates of future population were prepared separately for native whites, foreign-born whites, and colored, and therefore show changes in the relative size of these groups under the alternative assumptions of fertility and mortality. With respect to the proportion of foreign-born, the anticipated changes arise largely from the abnormal age distribution of the present foreign-born population and the assumptions regarding future immigration. To a lesser extent the

million at the most recent census. The subsequent trend to the end of the century will depend entirely on the course of mortality, being unaffected by births after the year 1935. On the assumption of a medium mortality the number in this age group may be expected to attain a maximum of somewhat over 21 million by 1990, declining only slightly in the following decade. The low mortality assumption raises the 2000 estimate to well over 25 million. Even under the high mortality assumption an eventual population of almost 20 million would be attained in the 65-and-over age group. In terms of percentage the 65-and-over section of the population more than doubled from three percent of the total population in 1870 to 6.8 percent in 1940. The medium assumptions yield a corresponding figure of 13.2 percent at the end of the century, compared to 11 percent under high fertility and medium mortality and 15.7 percent under low fertility and medium mortality.

Immigration at an average rate of approximately 100,000 per annum would have relatively minor effect on the proportion of the population in the 65-and-over age group. Under the medium assumptions immigration at the above rate would increase the number of persons aged 65 or more in the year 2000 by about half a million, but at the same time would fractionally decrease the percent of the total population in this age group.

Population under five years of age

The opposite aspect of the ageing of the population is the decrease in the proportion of young children. In 1870 children under 5 years of age constituted 14.3 percent of the enumerated population of the United States. This percentage declined gradually to 12.1 percent in 1900, and to 9.3 in 1930. By 1940 only 8 percent of the population was in the youngest age group. Under the medium assumptions a continued slow decrease is expected, with a figure of only 5.9 percent of the enumerated population estimated for the end of the century. Low fertility in combination with medium mortality would reduce this still further to 4.4 percent.⁹

⁹Assuming the same percent of under enumeration of children as estimated for 1940.

changes proceed from the assumption of continuing differentials of fertility and mortality between the foreign-born and the native born. Changes in the proportion of colored in the population arise from the fact, that, although it is assumed that the existing differentials of fertility and mortality will become narrower, the differentials are not expected to disappear even by the end of the century.

It must be reemphasized that no attempt was made to

predict the average volume of immigration or the number of the foreign-born in the United States. The series of estimates that included allowance for immigration were prepared as specimen computations, to indicate the effect on population trends of a unit amount of immigration and to permit the estimation of the influence of larger or smaller additions to the foreign-born population. With these reservations, some comments can be made on the indicated trends in the number and proportion of foreign-born residents in the United States.

FIGURE 9.—Trend of the foreign-born population, 1940 to 2000, under alternative mortality assumptions, with and without immigration.

The maximum number of foreign-born ever recorded in the United States was approximately 14,200,000 in 1930. The census of 1940 reported slightly over 11,400,000, the decrease presumably being due for the most part to an excess of deaths over immigration during the decade. In view of the heavy concentration of the present foreign-born population in the older ages, this group will inevitably decrease rapidly over the next few decades (see figs. 4 and 9). Under the medium assumption of mortality the present foreign-born group will be reduced to 5.9 million in 1960, and to about 1.7 million in 1980. Immigration averaging

about 100,000 per annum would not prevent the initial sharp drop in the number of foreign-born but would stabilize the number at somewhat under 5 million toward the latter part of the century.

Accompanying the downward trend in the number of foreign-born in the United States is a shift of the foreign-born to the older age groups. In 1940, 18 percent of the foreign-born were aged 65 or over, compared to under 6 percent of the native white population. Even with a resumption of immigration there will for some decades be an increasing concentration of the foreign-born at the older ages.

TABLE I 1.—Percent Distribution of the United States Population by Color and Nativity, with Selected Immigration Assumptions and with Medium Fertility and Mortality, 1940-2000

	1940	1960	1980	2000
Without immigration:				
Native white	81.1	85.0	86.6	86.1
Foreign born white	8.7	3.9	1.0	.1
Colored	10.2	11.1	12.4	13.8
Total	100.0	100.0	100.0	100.0
With 100,000 immigrants: ¹				
Native white	81.1	84.2	84.9	83.9
Foreign born white	8.7	4.9	3.0	2.9
Colored	10.2	10.9	12.1	13.2
Total	100.0	100.0	100.0	100.0
With 500,000 immigrants: ²				
Native white	81.1	81.1	79.1	76.9
Foreign born white	8.7	8.4	10.0	11.8
Colored	10.2	10.5	10.9	11.3
Total	100.0	100.0	100.0	100.0

¹ See section D for the explanation of the method of calculating the increase arising from this number of immigrants.

² This shows the effect of the entrance of 5 times as many immigrants as above.

The medium assumptions provide for a gradual increase in the colored population from the approximately 13½ million recorded in the census of 1940 to around 22 million in the year 2000. The percentage representation of the colored in the total population will depend somewhat on the volume of immigration, as shown in table I 1. Without immigration, the colored would make up 13.8 percent of the extended population at the end of the century. Immigration averaging around 100,000 per annum would reduce this figure to 13.2 percent.

J. DEMOGRAPHIC EFFECTS OF THE WAR

Although the war will have both temporary and lasting effects on trends of population in the United States, the extent of these effects and the precise form that they will take are largely unpredictable at the present time. The most that can be done is to indicate the probable direction of certain of the more readily predictable demographic changes, at the same time remembering that these are only a part of the war's effects on population. Among the immediate results that can be foreseen, it is obvious that military losses will directly affect population numbers and that these losses will be largely concentrated in certain age groups.

It is also clear that the losses, if of any considerable amount, will set up appreciable secondary changes in the size of the post-war generations. Irregularities in the age distribution will be produced by the large cohorts of births at the beginning of and immediately after the war and by any considerable deficit of births during the intervening period.

It is possible, without attempting to predict the extent of these and other anticipated changes, to indicate the approximate effect of arbitrarily assumed war losses and deficits of births. The procedure that was followed, as described in section E, was to prepare two

sets of correction tables, one set to be used in revising the estimates of future population when the total number of military losses becomes known at the end of the war, the other set to be applied when the net deficit of births during the war period can be estimated (see tables 14 to 19). Each set of tables was prepared in terms of a unit number of military losses or birth losses, the units being 100,000 for the white population, 10,000 for the colored. Both sets of correction factors were carried on up to the year 2000 under the assumption of high, medium, or low fertility in combination with medium mortality.

The population changes indicated by the correction tables reflect the assumptions on which the tables were based, such as the age distribution of the male losses, the continuance of the fertility trends unaltered after the war, the same percent of persons eventually marrying in the post-war as in the prewar period, and so forth. Under the medium assumptions the loss of the unit number of 110,000 males during the war would be gradually increased by the loss of their descendants, to diminish the estimated population of the year 2000 by 300,000. Under the same assumptions a net loss of an equal number of births during the period of the war would similarly be augmented to about 240,000 by the end of the century.

The direct war losses, assumed to be confined to males within the military age groups, would also disturb the sex ratio. Under the assumptions of medium fertility, medium mortality, and war losses distributed as in the previous war, the unit number of military losses would produce the following reduction in the number of males per 100 females.

Sex Ratio—1945

Age group	Without war losses	With war losses	De-crease	Age group	Without war losses	With war losses	De-crease
15-19.....	102.57	102.31	0.26	35-39.....	97.66	97.44	0.22
20-24.....	100.21	99.67	.54	40-44.....	98.25	98.17	.08
25-29.....	96.33	95.85	.48	45-49.....	100.00	99.98	.02
30-34.....	96.28	95.96	.32				

Larger or smaller losses would have proportionally greater or less effect on the sex ratio.

Marked fluctuations in the number of births will also be produced. If the war continues for some time the record number of births which occurred around 1942 will be succeeded by a considerable decline of the birth rate. Another peak of births will doubtless come after the war. As a consequence, school systems that have experienced a diminishing enrollment over a period of years will receive a wave of new pupils around 1945 to 1947, probably followed within a year or two by a marked decrease in the entering group, then by another wave beginning about 6 years after the end of the war. It can also be foreseen that the burden of new school enrollments will be very unequally distributed between different sections of the United States and between different types of communities. The burden will fall most heavily on communities that have received large accessions of war workers and that retain these workers for a time after the war. Areas in which the population has been more stable or more concentrated in the older age groups will experience little increase of school enrollment, and may be able to accommodate any increase that occurs within the existing school facilities.

Both sets of war loss correction tables provide for a decrease in the number of births in the future, in the first place because of the loss of potential parents during the war, in the second place because of reduction in the size of the post-war generation. These estimates, however, assume the continuance in the post-war period of the high, medium, and low trends of fertility unaffected by the war except for the somewhat smaller number of parents. It cannot be said to what extent the cultural patterns surrounding marital relations and the family will be changed after the war, but certainly they will be affected indirectly as well as directly. Some estimates can be made, as is done above, of the influence of war losses on trends of population, but this should not obscure the fact that the influence of the conditions of life in the post-war period will probably outweigh the influence of the direct losses.

IMPLICATIONS OF THE INDICATED POPULATION CHANGES

Estimates of the future population of the United States were published in 1937 in *The Problems of a Changing Population*. The present revised estimates are made at an interval of approximately 5 years later. During the intervening years there were significant changes in the distribution of fertility and mortality, but the outlook for the population of the United States remained much the same. Because of the favorable course of mortality and the definite rise of the birth rate during these years, the revised estimates run appreciably higher than the 1937 figures, yet under most combinations of fertility and mortality assumptions a gradual slowing down and an eventual cessation of population growth is still to be expected. Under certain sets of assumptions a decline of numbers will set in before the end of the century. In its essentials this is the population outlook that was presented in *The Problems of a Changing Population*.

The above refers to the population outlook as it stood in the early 1940's, before the outbreak of war. It remains to be seen if the pre-war trends of population are reestablished following the war or if new trends are set up. Any estimates of future population developments must therefore be qualified as being conditional on the effects of the war. At the same time, however, population is possessed of considerable inertia, for although vital rates change from year to year, the size and composition of a population at any given time are the composite effect of almost a century of births and deaths. This not only means that the direct effects of the war will be felt long after it is over; it also means that the course of population in the post-war period will continue to be strongly influenced by the fluctuations of the birth rate that took place during and after World War I, by previous immigration, and by other vital trends in the pre-war and inter-war period. The prospective population changes described in the preceding sections are for the most part inherent in the structure of the population as it is now constituted. Unless the war's direct impact on population far exceeds anything within the normal range of expectation, its effect will be to modify rather than to alter completely the demographic changes that are in prospect.

The basic demographic changes that are to be anticipated include a slowing down of the rate of natural

increase, an eventual cessation of population growth or even a decline under certain assumptions, and a marked change in the age distribution with a relative and absolute increase in the older ages. The probable social and economic consequences of these developments were discussed in a previous report, *The Problems of a Changing Population*, but some additional comment can be given.

It is generally believed that a decline in the rate of population growth or a cessation of growth would have far-reaching social and economic effects. The division of the total product of goods and services between the classical productive factors of land, labor, and capital would theoretically be affected. Per capita production might be affected by changes in the intensity of agriculture, in the supply of capital goods per worker, or in the strength of the tendency toward a diminishing of returns. Other effects of altered rates of population increase are ordinarily expected to be felt in terms of unemployment, urban and rural land values, the general standard of living, the rate of recovery from depression, and various other factors. These supposed effects of change in population trends, however, are usually based on the assumption that all other factors remain constant while population changes, and this is a condition that cannot be achieved in reality. It is more realistic to recognize that population changes occur only in conjunction with other changes of a social and economic character, and that the effects that are produced do not result solely from the population factor but rather from the total complex of conditions. In this total complex, however, population growth or decline may play an important part.

It is seen from the tabulated estimates of future population that the prospective changes will not have a sudden onset but will take place gradually. They are in fact already taking place. It therefore seems probable that whatever economic adjustments to the altered population situation may be needed can be made without any period of sudden and difficult transition, provided that they are envisaged and allowed for. It has been pointed out that an increase in per capita consumption can substitute for an increase of population, by providing an expanding demand for commodities. In other respects adjustments to a slowly chang-

ing population situation can doubtless be made without dislocation of the economic system, especially if the need for these adjustments can be anticipated and preparations made. In any event, it is doubtful if any future difficulties that the economic system may encounter will be attributable to population changes alone. At most, population trends may be expected to enter in as dynamic and complicating factors.

Although the indicated slowing down of the rate of population growth does not determine the pattern of future economic developments, various implications of this population trend can be pointed out. If the population of the country is to grow rather slowly for the next 40 or 50 years, perhaps beginning to decline somewhat thereafter, a number of readjustments will have to be made. For example, city planning will have to proceed more cautiously, for there will no longer be the same assurance of a continued growth. There will be less justification for the construction of permanent or semipermanent facilities, such as schools, water supplies, and sewerage systems, in excess of present needs on the assumption that they will eventually be brought into full use by a growing population. The per capita burden of long-term indebtedness will not be lightened as in the past by an increase in the number of taxpayers. Public utility systems will have the prospect of a more nearly constant number of customers. A similar situation will be faced by industry unless per capita consumption can be increased. The investment of capital for replacement will become more important relative to new investment for the expansion of capacity. Improvements in techniques of production and in the output per worker in both agriculture and industry will more directly affect the volume of available employment than has been true in the past.

Active changes in the distribution of both population and employment will certainly continue in spite of a trend toward stationary total numbers. Some areas will continue to attract an increasing number of residents, while other communities will decline in population. Regional differences in the rate of natural increase will persist, changing further the distribution of population and occasioning an active interstate and interregional migration. Changes in the location of industry and in the distribution of employment according to industry will likewise continue to cause shifts of population. It is in fact to be anticipated that a slowing down of the rate of population growth will considerably increase the relative importance of interregional movements of population.

It is probable that changes in the rate of population growth are of considerably less immediate significance than the accompanying changes in age composition. As outlined in section H above, the long-term trend is toward a decreasing proportion of children and an

increasing proportion of aged in the population. The immediate implications of this ageing of the population are for the most part apparent. With this change in the age composition of the population will doubtless come shifts in the distribution of the demand for commodities and services. Goods which children consume will become a steadily decreasing proportion of all consumer goods as children become a smaller and smaller proportion of the population. On the other hand there should not be much change in the proportion of our consumption in the most vigorous adult group, while there will be a very great and continuous increase in the demands of the middle-aged and older groups. There can be little doubt that these changes in the relative importance of different age groups will alter considerably our productive enterprise in the future. There will similarly be changes in amusement and recreational preferences. Diseases and infirmities of later life will come to demand a greater share of medical services, and there will be an expanding need for institutional facilities for the care of the aged. The changing age distribution will be directly reflected by the demands made on the Social Security system.

The catalog of the social, economic, and political consequences of an ageing population could be carried further, but for the most part these consequences follow quite directly from the changing age structure. The effects of the indicated population trends on the labor force of the United States, however, deserve special mention. In the early stages of the process at least, a declining fertility and an ageing population increase the fraction of the total population in the employable ages. If the age group from 15 to 65 is taken to include the bulk of all employables, then 57.7 percent of the population was of employable age in 1870. By 1900 this had increased to 61.3 percent, and in 1940 it was 68.1 percent. Under the medium assumptions of fertility and mortality this proportion would remain almost constant, declining only fractionally to 67.8 percent in the year 2000. A low level of fertility would raise this figure only several units, while a high level of fertility would reduce it by about the same amount. The outlook for the balance of the present century, therefore, is for a higher fraction of the population within the employable age group than during the nineteenth century.

Even though the proportion of the population between 15 and 65 years of age is to remain relatively high and stable for some years to come, there will be a considerable change in the age distribution within this group. In 1870 only 20.6 percent of the persons between 15 and 65 were 45 years of age or over. By 1940 this figure had risen to about 29 percent. Under the medium assumptions it will continue upward, reaching almost 39 percent by the year 2000. As compared to the

present figure, this represents an increase of about one-third in the proportion of older workers. It can therefore be foreseen that the problem of the older worker will take on added importance in the future. Industry may be forced to employ a greater proportion of workers over 45 years of age as the supply of younger workers becomes relatively more limited and as the supply of older workers increases. Other adjustments in productive enterprise will be made necessary by the changing age structure of the labor force, as well as by the associated changes in the demands for commodities.

In general, it is to be observed that although changes now under way in the structure and composition of the population of the United States do not in themselves necessarily determine the direction to be taken by social and economic events in the immediate future, they do nevertheless have the widest implications, and present situations for which many adjustments and new provisions may be necessary. Some of the more significant aspects of the prospective changes have been referred to above. Others can be inferred directly from the estimates of future population. In addition to the changing age structure and rate of population growth,

the sex ratio and the color and nativity composition of the population will be undergoing gradual changes, and each will have its direct and indirect consequences.

Finally, without attempting to indicate all the possible effects of current population trends, it can be emphasized that estimates of future population are an essential basis for a wide range of planning activities, both public and private, whether national, State, or local in scale. On the changing size, age structure, and composition of the population of the United States will depend in large measure the national manpower resources, the future needs for public utilities, housing and school facilities, and the nature and distribution of the demand for commodities and services, as well as in some measure the dimensions of the future problems of employment. It is therefore in the national interest to give careful attention to population trends, and to recognize that the prospective changes in the size and composition of the population are both a reflection of the many social, economic, political, and other developments that are taking place, and a major source of further change.
